

**Energy demand and energy-related  
CO<sub>2</sub> emissions in Greek manufacturing:  
assessing the impact of a carbon tax**

by

**Nikolaos Floros and Andriana Vlachou**

**Abstract**

The purpose of this paper is to study the demand for energy in two-digit manufacturing sectors of Greece and to evaluate the impact of a carbon tax on energy-related CO<sub>2</sub> emissions. The theoretical model utilized in the analysis is the two-stage translog cost function. The model is estimated using time series data over the period 1982-1998. The results indicate substitutability between electricity and liquid fuels (diesel and mazout), and substitutability between capital, energy and labor. A carbon tax of \$50 per tone of carbon results in a considerable reduction in direct and indirect CO<sub>2</sub> emissions from their 1998 level. This implies that a carbon tax on Greek manufacturing is an environmentally effective policy for mitigating global warming, although a costly one.

*Key words:* energy demand; CO<sub>2</sub> emissions; carbon tax; manufacturing

**Energy demand and energy-related CO<sub>2</sub> emissions  
in Greek manufacturing:  
assessing the impact of a carbon tax**

**1. Introduction**

In recent years the growing concern about the negative environmental impacts of energy production and consumption has revived the interest in studying the energy structure of different sectors of the economy. In particular, the combustion of fossil fuels is heavily implied for the rising concentrations of greenhouse gases in the earth's atmosphere which are expected to lead to significant changes in climate with serious economic and social effects (IPCC, 1996). Carbon dioxide (CO<sub>2</sub>) emissions are believed to be responsible for approximately half of the man-made contributions to the greenhouse effect. Accordingly, most of the efforts to mitigate global warming have concentrated on reducing CO<sub>2</sub> emissions.

CO<sub>2</sub> emissions account for the majority of the total greenhouse gases emissions in Greece since they were responsible for approximately 80.8% of the total emissions in 1998, while methane and nitrous oxide accounted for 8.6% and 7.5%, respectively. The combustion of fossil fuels accounted for 91% of total CO<sub>2</sub> emissions in the same year. CO<sub>2</sub> emissions increased by 18% between 1990-1998. The contribution of the industrial sector as an end-user to the total CO<sub>2</sub> emissions from fossil fuels (26% in 1998) was only second to the contribution of the domestic and tertiary sector (Ministry for the Environment and National Observatory of Athens, 2000). As result, the study of interfuel and interfactor substitution possibilities in Greek manufacturing can significantly help in designing effective policies to reduce CO<sub>2</sub> emissions.

A number of studies have investigated the demand of energy in Greek manufacturing (Caramanis 1979; Samouilidis and Mitropoulos, 1982; Vlachou and Samouilidis, 1986; Donatos and Mergos, 1989; Kintis and Panas, 1989; Caloghirou et al., 1997; Christopoulos, 2000; Christopoulos and Tsionas, 2002). However, most of these studies cover the period before 1990 and are conducted at a very aggregate level. Moreover, to the best of our knowledge, none of these studies was really

concerned with the environmental implications of the energy demand in manufacturing.

Greece, however, as a signatory of the UN Framework Convention on Climate Change in Kyoto, has certain obligations to fulfill jointly with the other member-states of the E.U. In particular, under the Kyoto Protocol, the E.U. is committed to a reduction of 8% of greenhouse gases from their 1990 level in the period 2008-12. The burden sharing arrangement for all member states, finalized in June 1998, allows Greece to increase its greenhouse emissions by 25% compared to 1990 levels. This target might not seem so restrictive at first sight. However, according to the Ministry for the Environment and the National Observatory of Athens (2000), total greenhouse gas emissions have already increased by 18% during the period 1990-1998. This implies that great efforts are needed in order to limit the increase to 25% by the year 2012.

The objective of this paper is to formulate and estimate a two-stage translog model using recent data in order to analyse intrerfuel and interfactor substitution in Greek manufacturing. The analysis is conducted at the two-digit level in order to avoid the shortcomings of aggregation. The estimated elasticities are then used to investigate the impact of a carbon tax on the energy-related CO<sub>2</sub> emissions from two-digit manufacturing sectors. Given the advantages of a carbon tax over alternative instruments (Pearce 1991; Vassos and Vlachou 1997a), the analysis provides an assessment of the possibilities for reducing CO<sub>2</sub> emissions from manufacturing to mitigate global warming in the case of Greece.

The paper is organized as follows. The second section presents in brief the theoretical model and discusses the data and the estimation technique. The third section reports and analyzes the empirical results. The final section is devoted to basic conclusions.

## **2. The Model and Data**

The econometric approach adapted in this study is a generalized translog production frontier, originally developed by Christensen, Jorgenson, and Lau (1973) and extensively applied in studies investigating the energy demand of industry (see, for example, Berndt and Wood 1975; Griffin and Gregory 1976; Fuss 1977; Pindyck 1979; Vlachou and Samouilidis 1986; Calogirou et al. 1997). In the context of this

methodological approach, we assume that there exists a twice differentiable aggregate production function for each two-digit manufacturing sector which relates the flow of gross output (Y) to the services of three inputs: capital (K), labor (L) and energy (E).<sup>1</sup> We further assume that the production function is weakly separable in the major categories of capital, labor and energy.<sup>2</sup> The assumption permits us to construct an energy price index that aggregates the prices of three fuels: electricity (EL), diesel (D) and mazout (M). Under these assumptions, the production function can be written as follows:

$$Y = f[K, L, E[EL, D, M], T] \quad (1)$$

where T is an index of technological change.

If the factor prices and output level are exogenously determined, this production structure can alternatively be determined by a cost function of the form

$$C = G[P_K, P_L, P_E (P_{EL}, P_D, P_M), Y, T] \quad (2)$$

where C is total cost, and  $P_K$ ,  $P_L$  and  $P_E$  are the input prices of K, L and E, respectively, while  $P_{EL}$ ,  $P_D$ , and  $P_M$  are the prices of electricity, diesel and mazout, respectively. Notice that  $P_E$  is the aggregate price index of energy which is homothetic in its arguments.

We represent the cost function (2) by a non-homothetic translog cost function.<sup>3</sup> By imposing symmetry on the second-order partial derivatives and assuming exogenously given input prices (as in the case of perfect competition), the translog cost function is specified as follows:

$$\begin{aligned} \ln C = & \alpha_o + \gamma_y \ln Y + 0.5\gamma_{yy} (\ln Y)^2 + \sum_{i=1}^n \beta_i \ln P_i + 0.5 \sum_{i=1}^n \sum_{j=1}^n \gamma_{ij} \ln P_i \ln P_j \\ & + \sum_{i=1}^n \gamma_{yi} \ln Y \ln P_i + \sum_{i=1}^n \gamma_{i\tau} T \ln P_i + \gamma_\tau T + 0.5\gamma_{\tau\tau} T^2 + \gamma_{y\tau} T \ln Y \end{aligned} \quad (3)$$

where  $i, j = K, L, E$

Shephard's lemma (Shephard 1953) implies  $\partial C / \partial P_i = X_i$ , the cost-minimizing quantity of the  $i$ th input. Then

$$\partial \ln C / \partial \ln P_i = P_i X_i / C = S_i,$$

and the input demand functions, in terms of cost shares  $S_i$ , take the form

$$S_i = \beta_i + \sum_{j=1}^n \gamma_{ij} \ln P_j + \gamma_{yi} \ln Y + \gamma_{it} T \quad (4)$$

where  $i, j = K, L, E$

The cost function must be homogeneous of degree 1 in prices, and satisfy the properties of a well-behaved cost function. In addition, the system of equations (4) must satisfy the adding up condition ( $\sum_i S_i = 1$ ). This implies the following parameter restrictions<sup>4</sup>:

$$\sum_{i=1}^n \beta_i = 1; \quad \gamma_{ij} = \gamma_{ji}; \quad \sum_{i=1}^n \gamma_{ij} = 0 \quad (5)$$

$$\sum_{i=1}^n \gamma_{iy} = 0, \quad \sum_i \gamma_{it} = 0$$

Two sets of elasticities can be calculated from the system of equations (4): i) the Allen partial elasticities of substitution  $\sigma_{ij}$ ; and ii) the factor price elasticities of demand  $\varepsilon_{ij}$ . The Allen elasticities are summarized as follows :

$$\begin{aligned} \sigma_{ii} &= (\gamma_{ii} + S_i^2 - S_i) / S_i^2 \\ \sigma_{ij} &= (\gamma_{ij} + S_i S_j) / S_i S_j, \quad i \neq j \end{aligned} \quad (6)$$

The price elasticities of demand are calculated as

$$\begin{aligned}\varepsilon_{ii} &= \sigma_{ii} S_i \\ \varepsilon_{ij} &= \sigma_{ij} S_j, \quad i \neq j\end{aligned}\tag{7}$$

We turn now to the derivation of the energy sub-model, which permits us to study interfuel substitution in two-digit manufacturing sectors and to construct the aggregate price index of energy to be used in equations (3) – (4). Since  $P_E$  is the price per unit of energy, it is also the cost per unit to the optimizing agent. This cost is represented by a homothetic translog function with constant returns to scale, which takes the form

$$\ln P_E = \alpha_0 + \sum_{i=1}^n \beta_i \ln P_{Ei} + 0.5 \sum_{i=1}^n \sum_{j=1}^n \gamma_{ij} \ln P_{Ei} \ln P_{Ej}\tag{8}$$

Cost-minimizing behavior implies that the demand functions for individual energy types, in terms of the cost shares in the cost of aggregate energy, take the form

$$S_{Ei} = \beta_i + \sum_{j=1}^n \gamma_{ij} \ln P_{Ej}, \quad i, j = EL, D, M\tag{9}$$

where  $S_{Ei}$  is the cost shares of the  $i$  fuel in the cost of aggregate energy,  $\sum_i S_{Ei} = 1$ .

The adding up criterion and the properties of neoclassical production theory require the following restrictions :

$$\sum_i \beta_i = 1; \quad \gamma_{ij} = \gamma_{ji}; \quad \sum_i \gamma_{ij} = 0\tag{10}$$

The Allen-Uzawa partial elasticities of substitution ( $\sigma_{ij}$ ) and the price elasticities of demand for each energy type can be calculated by using equations (6) and (7), respectively. However, these elasticities are calculated on the assumption that the total quantity of energy consumed remains constant. Dropping this assumption and following Pindyck (1979), we can estimate the *total* price elasticities for each energy type as follows :

$$\begin{aligned}\varepsilon_{ii}^* &= \varepsilon_{ii} + \varepsilon_{EE} S_{Ei} \\ \varepsilon_{ij}^* &= \varepsilon_{ij} + \varepsilon_{EE} S_{Ej} \quad , \quad i \neq j\end{aligned}\tag{11}$$

where  $\varepsilon_{EE}$  is the own price elasticity of aggregate energy (E), calculated from equations (3) and (4).

Estimation of the complete model is accomplished in two stages. In the first stage, we estimate the system (9) subject to the constraints (10). This provides an estimate of the interfuel substitution patterns. By substituting the parameter estimates into (9), we obtain an estimate  $\hat{P}_E$  of the aggregate price index (up to arbitrary scaling factor  $\alpha_0$ ). This estimate serves in the second stage. In particular, in the second stage, we estimate the system (4) subject to the constraints (5), replacing  $P_E$  by its estimate  $\hat{P}_E$ .

#### *Data and their sources*

The model described above was estimated for twenty two two-digit manufacturing sectors of Greece employing more than 10 employees, for the years 1982-1998. The main source of our data was the Annual Industrial Surveys (AIS) of the National Statistical Service of Greece (NSSG). Since the NSSG changed the industrial classification of several sectors in 1993, it was necessary to adjust the 1982-1992 data to the new classification to achieve continuity and compatibility for the time series.

The AIS provides data on total labor compensation and the number of workers employed. The AIS also provides data on energy. In particular, the expenditures and quantities of electricity, diesel and mazout consumed by the two-digit manufacturing sectors are available from this source, while the price for each energy type is calculated as the ratio of these two measures.<sup>5</sup> The quantity of each type of energy was converted into tons of oil equivalent (TOE).

In order to estimate the capital stock, we used the perpetual inventory method. Data on (gross) investment and depreciation at the two-digit level come from NSSG. The capital stock for the benchmark year (1982) of our study was obtained from the studies made by Skountzos and Mattheou (1991) and Georganta et al (1994)<sup>6</sup>. The

capital stock was estimated in constant 1982 prices by deflating gross investment and depreciation by the deflator of investment in fixed capital in manufacturing, provided by the NSSG. The return on capital was calculated from value added by subtracting from it total labor compensation. The price of capital was calculated by dividing the return on capital by the estimated net fixed capital.

Data on gross output comes from the AIS of the NSSG. Factor expenditures and prices, and gross production are deflated using the deflator of final manufacturing products for internal consumption, provided by the NSSG.

On the basis of the data collected for the study, we observe that in the majority of sectors, the energy share in total cost has been decreasing over the period 1982-1998. This seems to reveal a tendency of energy conservation and of substitution away from costly fuels by manufacturing firms, as Patsouratis and Souflias (1995) have also noticed. In particular, the energy share in the total cost of the sector in 1998 was 19.7% for sector 27, 15.4% for 26, 9.4% for 21 and 8.2% for 17. The most energy intensive sectors are the basic metal industries (27), the non-metallic mineral products (26), the pulp and paper (21), and the textiles sector (17).

Seven sectors (15,17,21,23,24,26,27) accounted for 91% of the energy consumption in manufacturing, as Table 1 shows. Almost all manufacturing sectors were electricity-intensive in 1998. This seems to be in part explained by the absence of natural gas from the energy balance of Greece prior to 1996. It might also indicate a substitutability between electricity and liquid fuels over the period. However, since a high percentage (65% in 1998) of electricity is generated by lignite-fired stations, a high electricity consumption by manufacturing tends to increase the CO<sub>2</sub> emissions produced in the country.

#### *Estimation technique*

For the estimation of the interfuel sub-model and the total cost (interfactor) model, the iterative Zellner method (or the seemingly unrelated regression estimation) was used. This method, which is equivalent to maximum likelihood estimation, gives consistent and asymptotically estimates.

**Table 1. The energy structure of Greek manufacturing in 1998  
(Selected sectors)**

| Code | Sectors                             | Sector's share in the energy consumption of manufacturing (%) | Fuel share in total energy consumption of the sector (%) |        |        |       |
|------|-------------------------------------|---|--|--------|--------|-------|
|      |                                     |   | Electricity  | Diesel | Mazout | Other |

| 27   | Basic metal industries              | 30.27   | 82.64  | 1.75   | 14.30  | 1.31  |
|      | Total                               | 91.02   | -  | -      | -      | -     |

Note: "other" includes lignite, coal and natural gas.

### 3. Empirical Results

#### *Interfuel sub-model*

Parameter estimates for the energy sub-model are presented in Table 2<sup>7</sup>. Most of the parameter estimates are statistically significant. In particular, 73.7 percent of estimated coefficients are statistically significant at 5% level of statistical significance, while 90 percent are statistically significant at 10%. The R<sup>2</sup>s for the share equations are fairly high when compared with similar studies<sup>8</sup>.

Table 3 presents own and cross price elasticities for the three energy types, estimated at the mean values of cost shares. The majority of the own price elasticities (with the exception of nine, of which six refer to mazout) are negative. Moreover, 76.5 percent of the own price elasticities are statistically significant at 5% level of statistical significance. Overall, the results suggest that the demand for electricity is inelastic to its own price changes in all sectors since the majority of own price elasticities are less than one. The demand for diesel is greater than one in eight sectors (17,23,25,27,28,29,35 and 36), while the demand for mazout is elastic in only three sectors (18,28, and 36). In short, the demand for diesel exhibits the highest price responsiveness among the three energy types.

The cross price elasticities suggest that electricity and diesel are substitutes in sixteen manufacturing sectors : 15,16,17,19,20,21,23,24,25,26,27,28,29,34,35 and 30. Only in three of these sectors (16,23,29) is this substitutability statistically insignificant at a level of 5%. Electricity and mazout are substitutes in eleven manufacturing sectors (15,16,17,18,21,23,24,27,28,31 and 36) and this relation is not statistically significant at a 5% level only in three of them (15,16,31). Between diesel and mazout, complementarily prevails since the cross price elasticity is negative in twelve sectors (15,17,19,20,21,24,25,26,28,31,34,36); however, in four sectors (21, 25,28 and 31), this complementary relation is insignificant at a 5% level. Overall, there is evidence that electricity and diesel as well as electricity and mazout are substitutes, while diesel and mazout are complements in most manufacturing sectors.

These results can be compared to previous studies. Vlachou and Samouilidis (1986) estimated own and cross price elasticities for electricity, liquid fuels and solid fuels in Greek manufacturing (aggregated in intermediaries, equipment, consumption and total manufacturing), using data for the period 1960-1980. The reported own price

Note: The figures in parentheses are the standard errors. The asterisk (\*) denotes that the elasticity is not statistically significant at 5%.

elasticities for electricity are: -0.308 in total manufacturing, -0.246 in intermediaries, -0.179 in equipment, and -0.125 in consumption. These estimates are very close to the own price elasticities of electricity estimated by this study. Vlachou and Samouilidis (1986) also reported the following own price elasticities for liquid fuels: -0.052 in total manufacturing, -0.015 in intermediaries, -0.309 in equipment, and -0.078 in consumption. These estimates are lower than the own price elasticities for diesel and mazout calculated by this study, suggesting a structural change away from liquid fuels in the 1980s and 1990s. It should be also mentioned that Vlachou and Samouilidis (1986) found that electricity and liquid fuels are substitutes in the three major manufacturing sectors. This result suggested, according to the authors, that manufacturing could move away from expensive imported liquid fuels by using electricity, produced by indigenous sources like lignite or renewable energy sources. This actually seems to have happened in the last three decades as captured by the increased share of electricity in the energy consumption of manufacturing.<sup>9</sup>

#### *Interfactor model*

The parameter estimates of the aggregate model are reported in Table 4. The majority (74 percent) of the estimated coefficients are statistically significant at a 5% level of statistical significance. The  $R^2$ s are very high implying that the cost shares, and for that matter the demand for the three productive factors, are fairly well explained by the translog specification.

Price elasticities, calculated at the mean values of cost shares, are presented in Table 5. All own price elasticities are negative, with the exception of two ( $\varepsilon_{kk}$  in sector 34, and  $\varepsilon_{EE}$  in sector 36).<sup>10</sup> Own price elasticities show that the demand for capital is inelastic in all sectors; when compared with the demand of labor and the demand of energy, it appears to be more inelastic than the latter in most sectors. The demand for labor is also inelastic in all sectors, except sector 17. The own price elasticities of energy are statistically significant in the majority of the sectors. They are less than one, with the exception of sectors 20, 22 and 26.

Although our estimates are not directly comparable to Christopoulos' (2000), we note with caution that our estimates of own price elasticities are higher (in most sectors) than the estimates provided by Christopoulos (2000) for aggregate

**Table 4. Parameter estimates of the total cost model, 1982-1998**

|    | Sectors   | $\beta_K$        | $\beta_E$          | $\beta_L$          | $\gamma_{KK}$    | $\gamma_{KE}$      | $\gamma_{KL}$     | $\gamma_{LE}$      | $\gamma_{LL}$     | $\gamma_{EE}$     | $\gamma_{LY}$      | $\gamma_{KY}$      | $\gamma_{EY}$      | $\gamma_{TK}$    | $\gamma_{TE}$      | $\gamma_{TL}$      | $R^2_{S_K}$ | DW<br>$S_K$ | $R^2_{S_E}$ | DW<br>$S_E$ |

Note: The figures in parentheses are the standard errors. The asterisk (\*) denotes that the elasticity is not statistically significant at 5%.

manufacturing using data for the 1970-1990 period. Christopoulos and Tsionas (2002), however, provided higher own elasticities which are much closer to ours. This might indicate structural changes which started in the 1980s and continued in the 1990s, leading to greater responsiveness of the demand of E, K, and L to price changes.

The estimates of cross price elasticities show that the productive factors are substitutes in the majority of the sectors. In particular, energy and capital are substitutes in sixteen of the twenty-two sectors under study; however, in six (of these sixteen) sectors, the cross price elasticity between K and E is not statistically different from zero. Labor and energy are substitutes in twenty sectors but in nine sectors  $\epsilon_{LE}$  is not statistically different from zero. As a result, an increase in the price of energy will lead to an increase in the demand for capital and labor as energy will be substituted by these two inputs in production. Capital and labor are substitutes in seventeen sectors but only in eight sectors is the cross elasticity between capital and labor statistically significant at a 5% level. All the cross price elasticities between capital, labor and energy are less than one, indicating weak substitutability or complementarity.

It should be noted that both our (disaggregate) study and Christopoulos' (2000), and Christopoulos and Tsionas' (2002) (aggregate) studies indicate an overall substitutability between K and E, E and L, and K and L in Greek manufacturing. Substitution possibilities are weak. However, our study suggests that they are stronger than those identified by Christopoulos (2000) and closer to those reported in Christopoulos and Tsionas (2002). Interestingly, Caramanis (1979) identified the same substitutability patterns. Moreover, Samouilidis and Mitropoulos (1982) and Donatos and Mergos (1989) also found substitutability between energy and capital in Greek manufacturing.<sup>11</sup>

#### *The impact of a carbon tax*

According to the Ministry for the Environment and the National Observatory of Athens (2000, 41), the industrial sector (extractive industry excluding energy, manufacturing and construction) accounted, as an end-user, for 26% of total CO<sub>2</sub> emissions from fossil fuels in Greece in 1998. About 45% of energy-related CO<sub>2</sub>

emissions in industry arised from the direct consumption of fossil fuels in order to meet industrial demands for steam and heat production, while the remaining 55% of industrial needs (operation of furnaces, ovens and lighting) are covered by electricity (ibid.).

Table 6 presents the contribution of each two-digit sector to total CO<sub>2</sub> emissions from manufacturing as an energy end-user in 1998 and it is based on the energy data collected for this study and on the emission factors provided by the Ministry for the Environment and the National Observatory of Athens (2000). We observe that the major CO<sub>2</sub> emissions contributors are sectors 26, 27, 15, 17, 24, 21 and 23. The table also presents the contribution of each energy type to total CO<sub>2</sub> emissions produced by each sector in 1998. We note that electricity is the major contributor in almost all sectors, a fact that is in tandem with the electricity-intensity of the Greek manufacturing mentioned before.

A number of policy instruments are available for reducing CO<sub>2</sub> emissions. One widely discussed option is the carbon tax (see, for instance, Poterba 1991; Pearce 1991; Commission of the European Communities, 1991, 1993; Agostini et al., 1992; Mabey and Nixon 1997; Vassos and Vlachou, 1997a; Shogren and Toman, 2000). For the case of Greece, to the best of our knowledge, a limited number of studies have investigated the impact of a carbon tax on the electricity supply industry (Vlachou et al 1996;Vassos and Vlachou 1997a,b) and on manufacturing (Patsouratis and Souflias, 1995).<sup>12</sup>

In our study, we investigate the impact of a carbon tax on CO<sub>2</sub> emissions from two-digit manufacturing sectors in 1998 on the basis of total price elasticities for each energy type calculated according to the formulae (11) and reported in Table 7. In estimating the impact of the tax, we take the structure of manufacturing as unchanged; this holds true as long as price changes are not large to induce a structural change. This means that only short-to-medium term (5-15 years) effects of a carbon tax can be analyzed and also that the carbon tax applied can not be too high. Furthermore, it should be noted that the impact of a carbon tax estimated in this way is only partial, given that our model is a static production/supply side model for manufacturing. Adjustments induced by the tax at the economy-wide level (which also react back on manufacturing) can not be captured by this model. Despite these restrictions, our modelling allows us to derive valuable results for manufacturing at a *disaggregate* level. This is quite important in view of the fact that ‘bottom-up’ and engineering

**Table 6: CO<sub>2</sub> emissions from manufacturing by sector and fuel, 1998**

| Code | Sectors   | Sector share (%) in total CO <sub>2</sub> emissions of manufacturing | Fuel share (%) in total CO <sub>2</sub> emissions of the sector |        |        |       |

studies advocate that there are unexplored opportunities for improvements in energy efficiency and for shifts to non-carbon intensive fuels.

Although we have applied different levels of carbon taxes on 1998 fuel prices (the last year of our study), for the sake of space we report here the results of a tax of \$50 per tonne of carbon.<sup>13</sup> Since the price of each energy type collected for this study differs by sector, a tax of \$50 per tonne of carbon leads to different increases in the price of the same fuel across sectors.<sup>14</sup> The results of a tax of \$50 per tonne of carbon are reported in the third column of Table 8 (‘*without* electricity restructuring’).<sup>15</sup>

A \$50 tax per tonne of carbon leads to an overall 17.6% reduction in CO<sub>2</sub> emissions from their 1998 level. In particular, the reduction in CO<sub>2</sub> emissions related to electricity consumed by total manufacturing is 19.1% from their 1998 level, the reduction related to diesel consumption is 8.6% and that related to mazout consumption is 11.3%. The overall 17.6% reduction in CO<sub>2</sub> emissions from their 1998 level decomposes into a 15.4 % reduction in CO<sub>2</sub> emissions related to electricity consumption and into a 2.2% reduction in CO<sub>2</sub> emissions related to liquid fuels consumption. These CO<sub>2</sub> reductions are the outcome of energy conservation, interfuel substitution, and energy substitution by other factors of production, all triggered by increases in energy prices due to the tax. However, the inelastic demand for energy inputs, the weak substitution possibilities, and the heavy dependence of manufacturing on electricity limit the effectiveness of the carbon tax in reducing *direct* CO<sub>2</sub> emissions from manufacturing.

Energy intensive sectors such as food and beverages (15), textiles (17), non metallic products (26) and basic metal industries (27), indicate high reductions in CO<sub>2</sub> emissions due to the tax. In particular, these four sectors account for the 88.3 % of the overall reduction in CO<sub>2</sub> emissions from manufacturing. For sectors 26 and 27, this reduction is mainly accounted by the reduction in electricity-related CO<sub>2</sub> emissions. For sectors 15 and 17, the reduction is both attributed to the fall in electricity and mazout related emissions.

These results clearly show the importance of targeting for reduction the CO<sub>2</sub> emissions generated by the electricity consumed by manufacturing. On the other hand, the observed reductions in *direct* emissions indicate that there do not exist ample low cost effective options for reducing CO<sub>2</sub> emissions from manufacturing. This conclusion is based on the well-established argument in environmental

**Table 8. The impact of a carbon tax of \$50 per ton of carbon on CO<sub>2</sub> emissions  
(Percentage reduction from 1998 CO<sub>2</sub> emissions)**

economics that a cost minimizing industrial firm tends to reduce its CO<sub>2</sub> emissions as long as its marginal control cost is less or equal to the tax per unit of emission. In our case, manufacturing firms, following this rule, are able to reduce direct CO<sub>2</sub> emissions (attributable to non-electric energy) from their 1998 level only by 2.2% at a marginal cost less or equal to \$50 per ton of carbon (or its equivalent of a \$13.5/tn CO<sub>2</sub>) - a cost level which is considered to be on the low side (see, for example, the Ministry for the Environment 2002, 77).

Renewable energy sources (RES), favored by a carbon tax, are also expected to have a significant contribution to reducing CO<sub>2</sub> emissions from manufacturing. It is interesting to notice that after the introduction of Law 2244/94, establishing incentives for investments in RES, and the Operational Program for Energy, funded by EU, there has been a growing interest for investing in wind energy, small hydro-electric production and in energy conservation by industrial firms.

As it has been noted above, our model estimated by time-series data is not able to capture the (direct) use of natural gas in manufacturing which started only recently, in 1997. However, the penetration of natural gas in manufacturing is expected to replace liquid fuels, especially mazout, and to promote the development of combined heat and power (CHP) generation systems, which have a high energy efficiency, in industrial firms with a high energy consumption. Previous studies (Vlachou et al. 1996; Vassos and Vlachou 1997a,b) have indicated that lignite generation in Greece can be replaced by natural gas, hydro and other renewable generating technologies as well as with coal or lignite technologies with CO<sub>2</sub> removal capabilities, all resulting in reducing CO<sub>2</sub> emissions.

To take into consideration the impact of electricity restructuring (effected independently from any carbon tax policy) on energy-related CO<sub>2</sub> emissions attributed to manufacturing, we accounted for changes in the fuel structure of power production (including natural gas generation), on the basis of the baseline projections of the National Action Plan (NAP) for 2010, officially provided by the Ministry for the Environment (2002). According to these projections, the share of natural gas in electricity generation increases from almost zero in 1995 to 28.4% in 2010. At the same time, the share of lignite generation decreases from 69.6% in 1995 to 47.5% in 2010; the share of liquid fuels decreases from 20.1% to 13%, while that of hydroelectric and other renewable generation remains almost the same, that is 10% in

1995 and 11% in 2010 (Ministry for the Environment, 2002, 26). As a result of these structural changes, the annual average growth rate of CO<sub>2</sub> emissions from electricity generation decreases from 3.1 % during the period 1995-2000 to 1.6% during the period 2000-2010. However, while the average factor of CO<sub>2</sub> emissions per MWh is reduced by the year 2010, at the same time the average cost per MWh increases by 11% approximately, according to our estimations on the basis of the NAP baseline scenario projections and the NAP cost data. When the carbon tax combines with this (independent) restructuring of electricity production, one expects it to become more effective in reducing energy-related CO<sub>2</sub> emissions from manufacturing; however, the cost burden on manufacturing also increases.

The results of a tax of \$50 per ton of carbon *with* electricity generation restructuring are reported in the fourth column of Table 8. A tax of \$50 per ton of carbon results in an overall 30.4% reduction in CO<sub>2</sub> emissions from their 1998 level. A portion of 92.8% of this overall reduction is attributed to electricity consumption and the rest (7.2%) to liquid fuels consumption. The four energy intensive sectors, 15, 17, 26, and 27 account for 82.2% of the overall reduction in CO<sub>2</sub> emissions from manufacturing. Despite the small own and cross price elasticities of electricity that characterize manufacturing, the impact of electricity price increases (due to its restructuring and the imposition of the carbon tax) and that of lower emissions factor are significant in scale, given the electricity-intensity of the sector.

To put our result in a comparative framework, let us now review the National Action Plan (NAP) of Greece to reduce Greenhouse Gas (GHG) emissions for the period 2000-2010 from their baseline level.<sup>16</sup> We are particularly interested in the level of emissions reductions to be achieved by the NAP and in the unit cost of abatement.

The NAP will reduce total GHG emissions in Greece by 12.4% from their baseline level in the year 2010. In particular, the NAP will reduce GHG emissions from electricity generation by 13.1 %. In industry (consisted of the extractive sector except from energy, manufacturing and construction), the NAP will reduce total GHG emissions in 2010 by 786 kt CO<sub>2</sub>-equivalent, i.e. a 5.1% reduction from their baseline level<sup>17</sup>; electricity generation's emissions attributed to the industrial sector through its consumption of electricity are included in the energy sector, not in industry.

The NAP also provides an estimate of the cost of the proposed measures to reduce GHG emissions in constant 1997 dollars (The Ministry for the Environment,

2002, 77). Measures with an average cost of less than \$30/tn CO<sub>2</sub> –eq (which is equivalent to \$110/t of C) are considered as low or medium cost measures. The average unit cost of a 5.1% reduction of industrial GHG emissions (in CO<sub>2</sub> –eq) from the baseline level in 2010 is \$ 43.2 /tn CO<sub>2</sub> –eq (which is equivalent to \$ 158.5/t of C). The average unit cost of a 13.1% reduction of GHG emissions (in CO<sub>2</sub> –eq) from the baseline level, discharged by electricity generation in 2010 is \$ 19.5 /tn CO<sub>2</sub> –eq (which is equivalent to \$ 71.6/t of C).<sup>18</sup> Combining the NAP findings for industry and electricity, the average cost per unit of reduction is estimated to be \$ 21.7 /tn CO<sub>2</sub> –eq (which is equivalent to \$ 79.5/t of C). In other words, 46.1% of the reduction of the national GHG emissions (in CO<sub>2</sub> –eq) from the baseline level in 2010 is achieved by electricity production and industry at an average unit cost of \$79.5/t of C (in 1997 dollars).

It is also interesting to refer to the study by Capros, Kouvaritakis and Mantzos (2001). These authors use the PRIMES Energy Systems Model, a modelling system which simulates a market equilibrium solution for energy supply in the European Union (EU) Member States, to investigate the cost-effective allocation of the GHG emissions reduction target for EU agreed in Kyoto (i.e. –8% from 1990 level by 2008-2012) under alternative scenarios. PRIMES is a static supply-side model, that is a model of a similar nature with our model. Industry in this study is subdivided into nine main sectors. Industrial boilers are allocated to industrial sectors. Emissions from electricity generation are, however, allocated to the energy sector, and not to industry (and other demand sectors) according to its consumption of electricity.

We present here the results of the burden sharing scenario (including the ACEA Agreement)<sup>19</sup>, assuming that each Member State achieves its burden sharing target alone.<sup>20</sup> The burden sharing agreement allows Greece to increase its GHGs emissions by 25.0% by 2008-2012.

For EU as a total, the results of this study indicate that a reduction of 10.2% in total industrial (fuel related) CO<sub>2</sub> emissions in 2010 from the baseline level can be achieved at a marginal abatement cost of 41.84 Eur('99)/tCO<sub>2</sub> (which is equivalent to Eur('99) 153.4/t of C, or to \$163.5/t of C in 1999 dollars). At the same marginal cost, the reductions from the 2010 baseline level by industrial sectors are as follows: iron and steel 9.9%; non-ferrous metals 8.0%; chemicals 12.4%; building materials 5.4%; paper and pulp 16.0%; food, drink and tobacco 11.6%; other industries 8.6%. Moreover, in the energy supply sector, a reduction of 13.3% in (fuel related) CO<sub>2</sub>

emissions in 2010 from the baseline level can be achieved at the same marginal abatement cost.

The results for Greece indicate that a reduction of 7.5% in total industrial (fuel related) CO<sub>2</sub> emissions in 2010 from the baseline level can be achieved at a marginal abatement cost of 11.11 Eur('99)/tCO<sub>2</sub> (which is equivalent to Eur('99) 40.74/t of C, or to \$43.42/t of C in 1999 dollars). At the same marginal cost, the percentage changes from the 2010 baseline level by industrial sectors are as follows: iron and steel -8.2%; non-ferrous metals -7.7%; chemicals -10.4%; building materials -5.0%; paper and pulp -11.8%; food, drink and tobacco -12.4%; other industries -8.1%. In the energy supply sector, a reduction of 12.5% in (fuel related) CO<sub>2</sub> emissions in 2010 from the baseline level can be achieved at the same marginal abatement cost.

There are considerable differences between the results of NAP, Capros et al. and our study. However, when compared to the other two studies, our results seem to fall within a reasonable range. They show in brief that a carbon tax of \$50/t of C in 1998 dollars, without any electricity restructuring, leads to an overall 17.6% reduction in CO<sub>2</sub> emissions (of which only 2.2% is reduction in direct emissions from manufacturing) from their 1998 level. When the carbon tax of \$50/t of C in 1998 dollars is combined with an (independently initiated) restructuring of electricity generation, it leads to a 30.4% reduction of (direct and indirect) CO<sub>2</sub> emissions from their 1998 level in manufacturing. This overall reduction decomposes into a 28.2 % reduction in CO<sub>2</sub> emissions related to electricity consumption and into a 2.2% reduction in direct CO<sub>2</sub> emissions from manufacturing. Assuming that manufacturing firms tend to cost-effectively equate the carbon tax to their (increasing) marginal cost of mitigation, our results seem to fall within the broad range of the marginal abatement cost estimates provided by the other two studies. Such comparisons, however, can only be quite rough because of the important differences in terms of underlying models, sectoral aggregation, type of emissions reductions targeted (i.e., total GHG as CO<sub>2</sub>-equivalent versus CO<sub>2</sub> energy-related), and because of the reduction options permitted by each model.

## 5. Summary and Conclusions

The purpose of this paper has been to empirically estimate the demand for energy in two-digit manufacturing sectors in Greece and evaluate the impact of a carbon tax on energy-related CO<sub>2</sub> emissions as a policy to mitigate global warming.

The empirical findings from the energy sub-model indicate that the demand for each energy type (electricity, diesel and mazout) is inelastic. The demand for diesel exhibits the highest price responsiveness among the three energy types. The cross price elasticities suggest that electricity and diesel, and electricity and mazout are substitutes, while diesel and mazout are complement in most manufacturing sectors.

In the aggregate translog model, all input demands are overall price-inelastic. The estimates of cross price elasticities indicate that the productive factors are substitutes in the majority of the sectors. Substitutability between energy and other factors of production suggest energy improvement and conservation possibilities for Greek manufacturing.

Imposing a tax of \$50 per tone of carbon, with no independently-initiated electricity restructuring, results in an overall 17.6% reduction in CO<sub>2</sub> emissions from their 1998 level. Significant reductions are evidenced in textiles, not metallic products, basic metal industries and pulp and paper sector. The increase in the energy prices due to the carbon tax induces energy conservation and improvement in energy efficiency, both resulting in a reduction of CO<sub>2</sub> emissions. The inelastic demand for energy inputs, the dependence of a manufacturing on lingite-generated electricity and the weak substitution possibilities limit the effectiveness of a carbon tax in reducing CO<sub>2</sub> emissions from manufacturing. When an electricity restructuring towards a less carbon-intensive production structure is permitted, the carbon tax becomes more environmentally effective. In particular, a tax of \$50 per tone of carbon results in a 30.4% decrease in total CO<sub>2</sub> emissions from manufacturing.

A carbon tax is expected to induce a further restructuring of the power supply industry, shifting away from high-carbon fuel technologies. At the same time, a carbon tax will give an incentive to manufacturing firms to use more natural gas and renewable energy resources, replacing, to some extent, conventional fuels.

In conclusion, the production structure of manufacturing sectors identified by our study suggests that there are considerable possibilities to reduce direct and indirect

CO<sub>2</sub> emissions if a carbon tax is used as a policy instrument. Since CO<sub>2</sub> emissions are the major contributor to the intensification of the greenhouse effect, the carbon tax is an effective instrument to mitigate global warming in the case of Greek manufacturing which is an electricity-intensive sector. However, the environmental effectiveness and cost-efficiency of a carbon tax with respect to the industrial structure need to be complemented by an analysis of its distributive and macroeconomic consequences (which have not been in the scope of the present analysis) when designing the tax.<sup>21</sup> This is especially true for Greece since a relative high carbon tax may have significant adverse economic effects, while the country's intervention will have a very limited impact on global warming.

## Endnotes

<sup>1</sup> We assume that capital, labor and energy inputs are as a group weakly separable from materials. This assumption was necessary since we had no data from which to construct price indices of materials.

<sup>2</sup> See Fuss (1977), Griffin and Gregory (1976), Pindyck (1979), Vlachou and Samouilidis (1986), Andrikopoulos, Brox and Paraskevopoulos (1989).

<sup>3</sup> The translog production function and cost function were introduced by Christensen, Jorgenson, and Lau (1973).

<sup>4</sup> Note that  $\sum_i^n \gamma_{iy} = 0$  does not impose homotheticity on the underlying production structure unless

each  $\gamma_{iy} = 0$  (see Fuss, 1977). Also note that  $\sum_{i=1}^n \gamma_{it} = 0$  implies a Hicks-neutral technical change.

<sup>5</sup> Natural gas appears to be used in manufacturing since 1997 so that we had to exclude it from our energy time series. In addition, we left coal out from our analysis since the data on it was missing for several years.

<sup>6</sup> Caloghiou et al. (1997) also used in their study, covering the 1980-1991 period, the capital stock provided by Georganta et al. at the two-digit level. In our study, we constructed our own series of capital stock for the period 1982-1998, taking only as a benchmark estimate the capital stock estimate of 1982 provided by Geoganta et al. (1994), and based on the previous study made by Skountzos and Mattheou (1991).

<sup>7</sup> Since sectors 30 and 32 use only electricity, an interfuel model is not estimated for these sectors. Moreover, results from the interfuel model are not reported for sectors 22 and 23. Due to the high share of electricity in these sectors, interfuel estimates are quite disturbing.

<sup>8</sup> See, for example, Vlachou and Samouilidis (1986) and Cristopoulos (2000).

<sup>9</sup> The results found by Christopoulos (2000) for aggregate manufacturing, using data for the period 1970-1990, are, more or less, similar to ours. He found an elastic demand for diesel and substitutability between diesel and electricity, both statistically significant; the demand for electricity was found to be inelastic, but the elasticity was not statistically different from zero.

<sup>10</sup> However, 34.8 percent of the own price elasticities are not statically different from zero at a 5% level of significance.

<sup>11</sup> Caloghirou et al. (1997) also provided results regarding substitutability between K, L, and E in Greek manufacturing. They concluded that "Allen elasticities show that all factors have high short-run substitutability. In the long run, capital and electricity are complements, as are labor and non-electric energy" (ibid, 490).

<sup>12</sup> The interesting analysis provided by Patsouratis and Souflias (1995) it is not based on any model estimation.

<sup>13</sup> Carbon factors per unit of fuel were obtained (as in the case of emission factors) from the Ministry for the Environment and the National Observatory of Athens (2000). This source is in compliance with the IPCC guidelines for national greenhouse gas inventories.

<sup>14</sup> In particular, the increase in the price of electricity, which is heavily reliant on lignite-fired production units, was significant, ranging from 20.5% to 26.9%. The increase in the price of mazout ranged from 21.4% to 27.4%, while the increase in the diesel price ranged from 7.0% to 9.7%.

<sup>15</sup> Notice that the estimates for sectors 22,30,32 and 33 are based on energy elasticities calculated by the interfactor models. As already mentioned, energy consumption in these sectors consists, almost in total, of electricity.

<sup>16</sup> The National Action Plan (NAP) to reduce Greenhouse Gas (GHG) Emissions for the period 2000-2010 was based on the projections of GHG provided by the Energy and Power Evaluation Program (ENEP) model developed by the Argonne National Laboratory (ANL, USA). See, the Ministry for the Environment (2002).

<sup>17</sup> This decrease in industrial GHG emissions decomposes in the following components: 163 kt CO<sub>2</sub>-equiv (20.7%) from natural gas penetration; 340 kt CO<sub>2</sub>-equiv (43.2%) from the use of solar energy replacing mazout and diesel; 46 kt CO<sub>2</sub>-equiv (5.8%) from substituting biomass to mazout; 238 kt CO<sub>2</sub>-equiv (30.2%) from various energy conservation measures.

<sup>18</sup> Moreover, the average unit cost of a 12.4% reduction in total GHG emissions (in CO<sub>2</sub>-eq) from the baseline level in 2010 is \$ 13.5 /tn CO<sub>2</sub>-eq (which is equivalent to \$50/t of C).

<sup>19</sup> The ACEA Agreement requires European, Japanese and Korean car manufacturers to market more fuel efficient vehicles.

---

<sup>20</sup> The results of the PRIMES model are combined with the bottom-up analysis carried out by Ecofys and AEA Technology to analyse the potential contribution of the different Member States and sectors in achieving the Kyoto target according to the burden sharing agreement.

<sup>21</sup> For a discussion of the modelling of macroeconomic effects of carbon taxes in general and in particular under alternative schemes of tax recycling, see, for instance, Mabey and Nixon (1997). With respect to the recycling of the carbon tax revenues back to manufacturing firms, it should be emphasized that it must not take a form that could reduce the environmental effectiveness of a carbon tax, especially when a certain emissions reduction target has to be achieved. Tax recycling should then take the form of a lump sum return or of a subsidy on the basis, for example, of the use of a renewable energy instead of a fossil fuel technology, and not affect the cost-effective behavior of manufacturing firms via the real after-the-recycling marginal abatement cost or tax burden.
